The distribution of Tertiary-Quaternary within-plate volcanic provinces throughout Europe is broadly anti-correlated with the location of a zone of high-velocity material within the Transition Zone at the base of the upper mantle (410-660 km depth), inferred to represent an accumulation of subducted slabs of oceanic lithosphere. Many of the major volcanic fields are located around the periphery of this velocity anomaly, coincident with the distribution of finger-like, slow velocity anomalies in the upper mantle, imaged by local seismic tomography experiments (e.g. Eifel, Massif Central). These anomalies have widely been considered to represent thermally anomalous “hotspots” or mantle plumes, some 100-150 °C hotter than the ambient upper mantle. However the absence of any evidence for a positive thermal anomaly at Transition Zone depths argues strongly against this. Indeed the Transition Zone is seismically fast – reflecting both the presence of high-velocity basaltic materials and, possibly, lower than ambient mantle temperatures.

An alternative explanation for these plume-like structures in the upper mantle is that they are the products of localised fluid streaming from the top of the Transition Zone. According to this model water is concentrated in the base of the upper mantle by subduction processes during the Africa-Eurasian collision and stored in high-pressure mineral phases. Periodic fluid release from the top of the Transition Zone (410 km), triggered by metamorphic break-down reactions, causes partial melting in the overlying mantle. Small degree partial melts of melilitic composition then rise towards the surface, causing further melting as they approach the base of the lithosphere. Localised extension within the lithosphere further enhances the degree of melting in some areas,

producing the range of nephelinites, basanites and alkali basalts observed.
